

Digital Payments, Formal Borrowing, and the Firm–Individual Boundary:

Evidence from Two Global Findex Waves

Nguyen Van Thong

University of Economics Ho Chi Minh City

Draft — September 18, 2026

Abstract

We examine whether the informational association between digital-payment activity and formal borrowing, documented at the firm level, generalises to individuals. Using Global Findex repeated cross-sections for a common frame of 93 economies observed in 2021 and 2024 — a sample and specification developed during exploratory analysis of the data rather than fixed by a prospective pre-registration — we estimate survey-weighted linear probability models with economy fixed effects and economy-clustered inference. Digital-payment activity is positively associated with formal borrowing in both waves, and its interaction with lower 2019 historical credit-reporting coverage is negative in 2021 (−1.74 percentage points; wild-cluster $p = 0.002$) and 2024 (−1.61 percentage points; wild-cluster $p = 0.020$) — the opposite of the sign a credit-information-substitution mechanism predicts. We then subject this reversal to two checks a genuine substitution channel should survive, and it survives neither. An identical interaction estimated on informal borrowing, a channel with no formal credit-information screening, is nonetheless positive and significant in both waves (+1.95, +1.75 percentage points) — evidence against a formal-credit-specific, information-screening interpretation of the reversal, though informal borrowing is not a clean negative control (it can still reflect social ties, reputation and selection). Allowing digital-payment activity to also interact with log GDP per capita and the account-ownership rate erodes the formal-borrowing interaction to non-significance in both waves on the full 93-economy sample, though this is consistent with severe collinearity between coverage and GDP per capita ($r = 0.74$ across the 93 economies) rather than with a cleanly identified competing channel; the erosion is not robust to excluding China and Saudi Arabia in 2021, where the interaction regains significance on the remaining 91 economies (§5.4). The result is an empirical puzzle rather than a confirmed boundary condition: a cross-level association observed consistently across both waves, whose two most natural explanations — an information-screening channel specific to formal credit, and a general economic-development channel — are, respectively, disfavoured by the evidence and not separately identifiable with this design. An inverse-probability-reweighting check further shows the 93-economy frame cannot be extrapolated to the higher-coverage economies the Findex module excluded. We identify no mechanism; account access, lender processing capacity, supply-side rationing, measurement and firm–retail lending-technology differences remain open explanations.

Keywords: digital payments, formal borrowing, credit information, financial inclusion,

1 Introduction

Digital payments can generate records that lenders may use when assessing borrowers. The economic question is not only whether payment activity correlates with credit access, but whether the informational value of that activity travels across lending contexts. The closest motivating benchmark is the firm-level study of Galilea, Farazi and Mare, which reports weaker firm credit constraints among electronic-payment users and a larger association in economies with weaker credit-information systems (Galilea et al., 2026). Their result motivates a substitution prediction: when conventional information is scarce, payment records should have greater marginal value.

Firms and individuals, however, do not face the same lenders, products, information technology or access margins. A firm outcome such as a self-reported credit constraint is also different from an individual’s realised formal borrowing. We therefore test whether the conditional pattern generalises to individuals using Global Findex evidence, on a common-economy specification developed during exploratory analysis of the data rather than fixed in advance of estimation. The 2021 and 2024 waves are repeated cross-sections, not an individual panel; 2017 is retained only as contextual/supplementary evidence because its payment measure is not a strict common exposure.

The primary result is a contrary one. Digital-payment activity is positively associated with formal borrowing, but the association is weaker in economies with thinner historical 2019 formal credit-reporting coverage. The inverse gradient is observed in both 2021 and 2024 under a qualified-comparable payment measure. The result is not confined to one economy under the leave-one-economy-out check and survives wild-cluster inference. This reversal is then run through two diagnostic checks a genuine formal-credit-specific information channel should survive — an informal-borrowing placebo and a set of macro-control interactions, both described in §5.4 — and it survives neither cleanly.

Our contribution is therefore not a boundary condition in the usual sense but evidence against a specific mechanism. The account motivating the search for this reversal — that digital-payment records substitute for scarce formal credit information in a way specific to formal, information-screened lending — does not survive a placebo test on informal borrowing, a channel with no such screening, though informal borrowing is not a clean negative control (it can still reflect social ties, reputation and selection). The account’s status once general economic development is accounted for cannot be separated from a design limitation rather than confirmed as a competing channel. We do not claim that the firm-level result is false, nor do we identify what does explain the individual-level reversal. The evidence remains compatible with account-access selection, general economic development, lender processing capacity, supply-side rationing, record usability, measurement and differences between firm and retail lending technologies — an empirical puzzle rather than a resolved mechanism.

2 Related literature and positioning

Global financial-inclusion measurement. The individual-level data underlying this paper come from the Global Findex Database, the household-survey program that underpins most cross-country evidence on account ownership, digital payments and borrowing behaviour (Demirgüç-Kunt et al., 2022; Klapper et al., 2025). Those reports document the digital-payment and formal-borrowing series used here and the module and country-coverage rules that generate the 93-economy common frame (§3); they do not themselves test a credit-information-substitution mechanism.

Firm and SME finance. Galilea, Farazi and Mare study firm credit constraints and electronic payments across economies, using Business Ready credit-information dimensions as institutional moderators (Galilea et al., 2026). Their unit, outcome, moderator and design differ from ours. The present paper is consequently an external-population and cross-level comparison, not a direct replication.

Experimental firm evidence also shows that lowering payment-adoption barriers can increase access to mobile loans for SMEs (Dalton et al., 2024). This supports the economic relevance of payment technology in business finance, but does not establish the same boundary for retail borrowing.

Digital footprints and lender information. Digital footprints can complement rather than substitute for bureau information in predicting consumer default in a single-lender setting (Berg et al., 2020). Recent lender-level evidence uses applications, payment histories, approval, pricing and default outcomes to study the informational content of cashless payments (Ghosh et al., 2026). These studies clarify what is needed to identify information value or lender use; the Findex design does not observe those links.

Positioning. We make no categorical first claim. The paper contributes a transparent individual-level test, developed through exploratory analysis of the data and subsequently independently reproduced (Stage 12), whose inverse gradient is observed in both recent waves. It is a descriptive boundary-condition result and a theory-generating puzzle, not an identified mechanism or causal institutional effect.

3 Data and measurement

The primary frame contains 93 economies common to the 2021 and 2024 Global Findex waves (World Bank, 2025; Demirgüç-Kunt et al., 2022; Klapper et al., 2025) and 194,558 respondents. The 2024 baseline is 97, not the raw release’s 140, because the borrowing/digital-payment module was administered in only 97 economies; the 93-economy frame is the intersection of that 97-economy set with the 139 economies in the 2021 raw release, after also requiring complete primary covariates. This module-administration rule is not neutral with respect to the moderator: of the 133 economies present in both raw 2021 and 2024 releases, the 40 excluded from the 93-economy frame are overwhelmingly high-income economies (for example Australia, Canada,

France, Germany, Japan, Korea, Switzerland, the United Kingdom and the United States) with near-universal 2019 credit-information coverage — 24 of the 34 economies worldwide with 2019 coverage at or above 95% are excluded from the 93-economy frame, and the moderator’s interquartile range is compressed in-sample (11.7 to 60.7) relative to the excluded-but-data-available pool (1.2 to 92.6). The 93-economy sample is therefore not a random or exhaustive cross-section of economies with available 2019 coverage data; it is a population pre-filtered by Findex fieldwork decisions that are plausibly correlated with the same financial-system completeness the moderator is meant to capture. Findex waves are repeated cross-sections. The 2021 release’s interview-year field includes some observations interviewed in 2022; they remain part of the official 2021 survey wave and are not silently reclassified.

The outcome (**fin22a**) is a single self-reported item — “In the past 12 months, have you borrowed any money from a bank or a similar financial institution?” — rather than a constructed aggregate of named credit products; its “or a similar financial institution” phrasing leaves some interpretive latitude to respondents about what counts as formal, which this paper does not attempt to resolve further. The exposure is the qualified-comparable 2021–2024 digital-payment measure documented in the harmonisation audit. It is not described as an invariant causal treatment. The 2017 payment reconstruction is contextual only.

The moderator is the maximum of private-bureau and public-registry coverage in 2019, standardised so that larger values denote thinner historical formal credit-reporting coverage. It measures breadth of recorded coverage, not information depth, accessibility, legal usability or actual lender use. Coverage, depth and accessibility therefore remain separate constructs. This series is drawn from the archived World Bank Doing Business “Getting Credit” indicators (World Bank, 2019) (the same 2019-vintage snapshot used in the frozen H-000500/H-000501 single-wave design), which the World Bank paused and later discontinued in 2021 after an internal review found data irregularities in a subset of country scores (World Bank, 2020), publicly confirmed for China (DB2018) and Saudi Arabia (DB2020) — both present in this 93-economy sample. Whether the archived 2019 values used here reflect pre- or post-review figures for the affected economies is not established from the files available to this project; this is disclosed as a provenance uncertainty, not a demonstrated error, consistent with the same disclosure already carried in the H-000500/H-000501 manuscript. Excluding China and Saudi Arabia and re-standardizing the moderator over the remaining 91 economies leaves the primary interaction negative and significant in both waves (−1.64 pp in 2021, wild-cluster $p = 0.001$; −1.54 pp in 2024, wild-cluster $p = 0.007$; changes of 5.7% and 4.3% relative to the 93-economy estimates), so the registered reversal is not driven by the two in-sample economies with documented *Getting Credit* irregularities. This does not validate the Doing Business production process for the remaining 91 economies or rule out general moderator measurement error.

Account ownership is retained as an access/selection-sensitive variable. The primary specification does not condition on it. Conditioning or restricting to account holders is a sensitivity estimand that may remove part of the access pathway or create collider risk; it is not a universally superior control specification.

4 Empirical strategy

For each wave $w \in \{2021, 2024\}$, the primary model is a survey-weighted linear probability model with economy fixed effects:

$$Y_{icw} = \beta_{1w}D_{icw} + \beta_{3w}(D_{icw} \times L_c^{2019}) + X_{icw}\gamma_w + \delta_{cw} + \varepsilon_{icw},$$

where D is qualified-comparable digital-payment activity, L^{2019} is the fixed historical low-coverage moderator, and X contains the frozen demographic controls: a female indicator, a centered age quadratic (age and age²), and categorical education and income-quintile indicators. Weights are the official wave-specific weights normalised within economy-wave; no pooled survey weight is created. Inference clusters at the economy level. Interaction inference uses a null-imposed, cluster-score Rademacher bootstrap (999 replications) that reconstructs the coefficient distribution from a fixed bread matrix computed once at the unrestricted fit, rather than refitting the model on every replicate; this is referred to below as the wild-cluster bootstrap, following common usage, though it is a one-step score-bootstrap variant and not a full-refit Cameron–Gelbach–Miller wild-cluster bootstrap.

The pooled model is secondary and descriptive. It includes wave indicators and the payment-by-wave and payment-by-low-coverage-by-wave terms. Since L_c^{2019} does not change between 2021 and 2024, the triple interaction is a cross-wave conditional contrast, not an effect of institutional change.

The primary estimands are the wave-specific association and wave-specific coverage gradient. The difference between gradients is described only as a temporal contrast; coefficient equality is not asserted because no new equality test was pre-specified.

5 Results

5.1 Primary two-wave evidence

Digital-payment activity is positively associated with formal borrowing in both waves. The payment-by-low-coverage interaction is negative in both primary separate-wave models: -1.74 percentage points in 2021 and -1.61 percentage points in 2024. The wild-cluster bootstrap p-values are 0.002 and 0.020, respectively. These are conditional associations, not causal effects. Table 1 reports the primary estimates.

The repeated appearance of the inverse gradient makes a one-year anomaly explanation less plausible. But two-wave persistence does not distinguish a recurring economic relationship from a recurring selection structure, measurement structure or institutional composition. It does not prove temporal stability, equality, a structural effect or a common mechanism. Every one of the 93 leave-one-economy-out estimates remains negative in each wave, with ranges of approximately $[-1.97, -1.56]$ pp in 2021 and $[-1.83, -1.27]$ pp in 2024. Because the primary weighting gives each economy equal aggregate weight, dropping any single economy removes only about one ninety-third of total estimation weight, which mechanically narrows this range; sign preservation across all 93 single-economy deletions rules out a dominant-influence economy, not homogeneity of the underlying association across economies or economy groups.

Table 1: Primary separate-wave estimates, 2021 and 2024

	2021	2024
Digital payment association (pp)	9.07***	8.13***
Payment $\times$ lower 2019 coverage (pp)	-1.74***	-1.61***
Clustered SE, interaction (pp)	(0.49)	(0.60)
Wild-cluster p , interaction	0.002	0.020
Observations	96,711	97,847
Economies	93	93

Notes. Survey-weighted WLS linear probability models with economy fixed effects and economy-clustered standard errors. The exposure is qualified-comparable across 2021–2024, not asserted to be perfectly invariant. Coefficients are percentage points. Wild-cluster inference uses 999 null-imposed cluster-score Rademacher replications. *** denotes clustered $p < 0.01$, ** $p < 0.05$, * $p < 0.10$. Generated by `code/study_05_crosscountry/tables/build_stage8_tables.py` from `results/stage5_estimation/estimates.csv` and `results/stage5_1_reconciliation/wild_cluster_bootstrap.csv`.

5.2 Pooled contrast and reconciliation

The pooled secondary interaction is -1.98 percentage points. The 2024 triple interaction is $+0.58$ percentage points, with wild-cluster $p = 0.305$ (Table 2). Thus the specified pooled model finds no statistically detectable wave difference in the conditional gradient. This is not proof that the two coefficients are identical.

Table 2: Secondary pooled repeated-cross-section parameterization

Term	Estimate (pp)
Payment $\times$ lower 2019 coverage	-1.98***
Payment $\times$ lower coverage $\times$ 2024	+0.58
Wild-cluster p , triple interaction	0.305
Observations	194,558
Economies	93

Notes. This is a descriptive pooled parameterization. The 2019 moderator is fixed across waves, so the triple interaction is a temporal contrast and not an institutional-change effect. The pooled-implied gradients need not equal the separate-wave coefficients because nuisance slopes and interaction terms are jointly estimated on the pooled sample. *** denotes clustered $p < 0.01$, ** $p < 0.05$, * $p < 0.10$; the triple interaction is not significant at conventional levels. Generated by `code/study_05_crosscountry/tables/build_stage8_tables.py` from `results/stage5_estimation/estimates.csv` and `results/stage5_1_reconciliation/wild_cluster_bootstrap.csv`.

The pooled-implied 2021 gradient is -1.98 pp and the pooled-implied 2024 gradient is -1.40 pp. They do not equal the separate-wave estimates mechanically because the pooled regression jointly estimates the interaction terms with common nuisance slopes, pooled sample composition and the pooled fixed-effects parameterisation. The separate-wave estimates remain primary.

5.3 Institutional dimensions and account sensitivity

Depth is analysed separately from coverage and is secondary evidence. Accessibility is a validation/context layer rather than a comparable primary moderator in the frozen dataset. The evidence therefore does not establish a general institutional gradient across all dimensions.

The account-ownership sensitivity is read only as selection/access sensitivity. Conditioning on account ownership slightly attenuates the interaction in 2021 and makes it more negative

in 2024. This cross-wave difference does not identify account access as the mechanism. In the 2021 wave specifically, approximately 3% of `account_fin` = 1 respondents are constructed from payment- or card-derived evidence rather than the standard account-screening questions, so `account_fin` and `digital_payment` share a small construction overlap in that wave — a first-order collinearity risk for the account-conditioning specification in 2021 specifically, distinct from the selection-versus-mechanism caveat above.

5.4 Additional robustness: external-validity reweighting and macro-control interactions

Two further exploratory checks quantify, rather than only narrate, two threats already raised above and in the Limitations: the module-administration sample restriction, and the possibility that the coverage moderator proxies general economic or financial development. Neither check is pre-registered or confirmatory; both are diagnostic, following the same inverse-probability-weighting protocol already used for the frozen H-000501 record’s Q5 module-selection check, adapted to the present two-wave frame. Table 3 reports both.

External-validity reweighting. Restricting to the 132 economies with usable economy-level covariates among the 133 present in both raw 2021 and 2024 releases (Taiwan is dropped for missing all covariates, as in the frozen H-000501 precedent), an inclusion logit on 2019 coverage, log GDP per capita, region and log adult population separates the 93 included from the 39 excluded economies with a *c*-statistic of 0.982 (5-fold cross-validated mean AUC 0.954), indicating the near-complete separation reflects a genuinely strong inclusion rule — not overfitting on 132 economies with four predictors — so it is read as a description of the selection process rather than a numerically unstable fit; inverse-probability weights are trimmed at the 1st/99th percentiles (maximum trimmed weight 6.44, Kish effective sample size 60.9 of 93) before reweighting. Reweighting the 93-economy sample by the inverse inclusion probability keeps the coverage interaction negative and of similar magnitude in 2021 (primary -1.74 pp; reweighted -1.77 pp, a 1.3% change, wild-cluster $p = 0.002$) and attenuates it further in 2024 (primary -1.61 pp; reweighted -1.23 pp, a 23.3% change, wild-cluster $p = 0.043$), in both cases well inside the $\pm 50\%$ stability band. The classification is nonetheless **not credibly transportable with the available covariate overlap**, not because the reweighted point estimates are unstable, but because 80 of the 132 economies fall outside common support — the excluded, mostly high-coverage economies are sufficiently different in covariate profile from the included 93 that no amount of reweighting can credibly extrapolate to them. This is the same qualitative outcome, and a similar outside-support count, as the frozen H-000501 Q5 check on a different target frame, which strengthens the reading that the module-administration restriction is a genuine, not incidental, limit on external validity.

Macro-control interactions. Because `lowcov_z` interacted with log GDP per capita or the account-ownership rate is collinear with the economy fixed effects already in M2 (both terms are constant within economy), the diagnostic instead interacts `digital_payment` with these two economy-level covariates — the same construction already used for the primary interaction — and asks whether `dig_x_lowcov` survives. It does not survive at conventional significance: the coefficient attenuates from -1.74 to -1.21 pp in 2021 (30.9% change, $p = 0.087$, no longer

significant at 5%) and from -1.61 to -0.98 pp in 2024 (39.0% change, $p = 0.31$, not significant), while remaining negative in sign in both waves. Neither new interaction term itself reaches conventional significance (payment $\times$ log GDP per capita: $p = 0.75$ and $p = 0.64$; payment $\times$ account-ownership rate: $p = 0.14$ and $p = 0.07$). Part of this attenuation is mechanical rather than substantive: the 2019 coverage moderator and log GDP per capita are themselves highly correlated across the 93 economies ($r = 0.74$, $R^2 = 0.55$), so asking the model to identify both the coverage and the GDP-per-capita interaction terms simultaneously, with only 93 economy-level clusters, imposes a severe collinearity burden regardless of whether a genuinely separable development channel exists — consistent with neither new interaction term itself reaching significance. Excluding China and Saudi Arabia and re-standardizing the coverage and GDP-per-capita moderators over the remaining 91 economies changes the 2021 significance conclusion specifically: the coverage interaction is -1.38 pp and *regains* conventional significance ($p = 0.039$, versus $p = 0.087$ on 93 economies); in 2024 it is -0.95 pp and remains non-significant ($p = 0.33$), consistent with the 93-economy result. `dig_x_lgdppc` and `dig_x_accrate` remain non-significant in both waves on 91 economies. The claim that macro-controls erode the coverage interaction to non-significance in *both* waves therefore holds only on the full 93-economy sample; on the 91-economy sample it holds for 2024 only, while 2021 retains significance once China and Saudi Arabia are excluded. This is not evidence that the two economies’ disclosed *Getting Credit* irregularities drive the primary result — §3 shows the primary two-wave interaction is robust to their exclusion in both waves — but it does mean the macro-control erosion is more sensitive to sample composition than the primary interaction is, and the "non-significant in both waves" language elsewhere in this paper describes the 93-economy specification, not a sample-invariant finding. This is reported plainly rather than softened: with this degree of correlation and this many clusters, the design cannot cleanly distinguish a credit-information-specific channel from a general economic-development channel. The attenuation is consistent with either genuine confounding or with collinearity-driven loss of precision, and the data cannot adjudicate between the two. We therefore do not claim the coverage interaction is spurious, only that its specificity to credit-information coverage, as opposed to economic development more broadly, is not identified by this design.

5.5 Placebo check: informal borrowing

A further exploratory check asks whether the coverage interaction is specific to formal borrowing or also appears for an outcome the substitution reading predicts should be unaffected: borrowing from family or friends (`informal_borrow`, from `fin22b`), constructed exactly as in the frozen H-000500 record and re-estimated under the identical M2 specification, weighting and wild-cluster inference used throughout. The row-level sample reconstruction was validated against `results/stage5_estimation/estimates.csv` before this check was read: both waves’ complete-case N and G match the primary formal-borrowing sample exactly (96,711/93 in 2021, 97,847/93 in 2024), confirming the reconstruction is faithful; `informal_borrow`’s own missingness (dropping `fin22b` DK/refused) then yields a slightly smaller estimation sample (96,535 and 97,723 respondents, still 93 economies in both waves). Table 4 reports both waves.

The placebo does not pass. As with the frozen H-000500 record’s own informal-borrowing

Table 3: Stage 17 additional robustness: external-validity reweighting and macro-control interactions

<i>Panel A: IPW reweighting toward the 39 excluded, mostly high-coverage economies</i>		
	2021	2024
Primary $\times$ lower-coverage interaction (pp)	-1.74	-1.61
IPW-reweighted interaction (pp)	-1.77	-1.23
Clustered SE, reweighted (pp)	(0.51)	(0.64)
Wild-cluster p , reweighted	0.002	0.043
Relative change vs. primary	1.3%	23.3%
Inclusion logit c -statistic: 0.982; economies outside common support: 80 of 132		
Max IPW weight after 1st/99th trim: 6.44; Kish ESS: 60.9 of 93		
Classification: not transportable		
<i>Panel B: digital-payment interactions with log GDP per capita and account-ownership rate</i>		
	2021	2024
Payment $\times$ lower coverage (pp), with macro controls	-1.21*	-0.98
	(0.70)	(0.97)
Payment $\times$ log GDP per capita (pp)	-0.24	-0.35
	(0.76)	(0.74)
Payment $\times$ account-ownership rate (pp)	1.17	1.29*
	(0.79)	(0.73)
Primary (no macro controls) interaction (pp): -1.74 (2021), -1.61 (2024)		

Notes. Panel A: inverse-selection weighting ($1/\hat{p}$, trimmed at the 1st/99th percentile, combined multiplicatively with the primary economy-equal weight), following the same protocol as H-000501's Q5 module-selection check, adapted to a different target frame (economies present in both raw 2021 and 2024 Findex releases). Classification follows the same three-way rule: *stable* requires adequate common support; the 80-of-132 economies outside common support here force *not transportable* regardless of the reweighted point estimate's own stability. Panel B: `digital_payment` $\times$ `log-GDP-per-capita` and `digital_payment` $\times$ `account-ownership-rate` terms are added *in place of* lower-coverage interactions with these macro covariates, because the latter are collinear with the economy fixed effects already in M2 (both a covariate constant within economy and its interaction with another economy-constant covariate are absorbed by `C(economycode)`). *** denotes clustered $p < 0.01$, ** $p < 0.05$, * $p < 0.10$. Both panels are exploratory/diagnostic robustness, not pre-registered or confirmatory. Generated by `code/study_05_crosscountry/tables/build_stage8_robustness_table.py` from `results/stage17_external_validity/`.

check, the coverage interaction on informal borrowing is **positive**, not approximately zero: +1.95 percentage points in 2021 (wild-cluster $p = 0.009$) and +1.75 percentage points in 2024 (wild-cluster $p = 0.006$) — opposite in sign to the $-1.74/-1.61$ percentage-point formal-borrowing interaction, and, unlike H-000500’s single-wave version of this check, now replicated with a similar magnitude and precision in both waves of a fully separate design. This is reported plainly rather than reconciled: the data are consistent with a reallocation of borrowing activity toward informal sources where coverage is thinner, but this check alone does not establish that reading, since it does not observe the same individuals borrowing from both sources or rule out a shared measurement or selection process behind both outcomes. It does, however, further undermine any reading of the formal-borrowing interaction as confirming the credit-information-substitution prediction: a genuine substitution effect specific to formal, information-screened lending should not also show up, with similar strength and in the same two waves, for borrowing that involves no credit-information screening at all. Excluding China and Saudi Arabia and re-standardizing the moderator over the remaining 91 economies leaves this placebo interaction positive and significant in both waves (+1.81 pp in 2021, +1.69 pp in 2024, both wild-cluster $p < 0.03$; changes of 7.1% and 3.9% relative to the 93-economy estimates), so it is not an artifact of the two economies with disclosed *Getting Credit* irregularities either.

Table 4: Placebo check: informal borrowing, 2021 and 2024

	2021	2024
Digital payment association (pp)	+9.71***	+9.50***
Payment $\times$ lower 2019 coverage (pp)	+1.95***	+1.75***
Clustered SE, interaction (pp)	(0.72)	(0.59)
Wild-cluster p , interaction	0.009	0.006
Observations	96,535	97,723
Economies	93	93

Notes. Outcome is `informal_borrow` (borrowed from family or friends in the past 12 months), constructed from `fin22b` exactly as in the frozen H-000500 record. Same M2 specification, weighting and null-imposed cluster-score Rademacher wild-cluster inference (999 replications) as the primary formal-borrowing model. *** denotes clustered $p < 0.01$, ** $p < 0.05$, * $p < 0.10$. Generated by `code/study_05_crosscountry/tables/build_stage8_placebo_table.py` from `results/stage18_placebo/informal_borrow_estimates.csv`.

6 Discussion

The central empirical fact is that the inverse digital-payment/formal-borrowing gradient is observed in both recent Findex waves. The two-wave result reduces the likelihood of a one-wave anomaly, but it does not by itself identify an underlying economic mechanism: the same persistent selection or measurement structure could recur.

Two-wave persistence, however, is not the paper’s strongest result. Two checks were run specifically to ask whether the reversal reflects the credit-information-substitution mechanism the literature motivates, and both point away from it. The informal-borrowing placebo (§5.4) finds the identical interaction, on a channel with no formal credit-information screening, positive and significant in both waves — the opposite of what a mechanism specific to formal, information-screened lending would produce. This is evidence against that specific interpreta-

tion, not merely a failure to confirm it: the formal-credit-specific account predicts a near-zero placebo interaction, and instead the placebo interaction is of similar magnitude and precision to the formal-borrowing result, with the opposite sign — though informal borrowing is not a clean negative control, since it can still reflect social ties, reputation and selection unrelated to credit-information screening. Separately, allowing digital-payment activity to interact with log GDP per capita and the account-ownership rate (§5.4) erodes the formal-borrowing interaction to non-significance in both waves on the full 93-economy sample; because 2019 coverage and log GDP per capita are themselves correlated at $r = 0.74$ across the 93 economies, this is consistent with either a genuine development-level channel or with the two variables simply being too collinear, given 93 clusters, for the design to tell them apart. This erosion is itself sample-sensitive: excluding China and Saudi Arabia, the 2021 interaction regains significance ($p = 0.039$ on 91 economies versus $p = 0.087$ on 93), while the 2024 result is unchanged (§5.4); the non-significance claim should therefore be read as specific to the 93-economy specification rather than as a sample-invariant finding, which further limits how much weight the macro-control check can bear relative to the placebo. Taken together, these checks leave the reversal itself observed consistently across both waves, but its two most natural explanations — a credit-information-specific channel, and a general-development channel — respectively disfavoured by the evidence and unidentifiable. The paper’s contribution is therefore best read as an empirical puzzle: a pattern that recurs across both waves and resists the mechanism motivating the search for it, not a confirmed boundary condition with an unresolved but plausible cause.

This finding also describes a narrower population than “cross-country” evidence might suggest. The 93-economy frame excludes most near-universal-coverage economies because the underlying survey module was not administered there, not because moderator data are missing (see Data); the boundary-condition and transportability language in this paper should therefore be read as describing module-administered economies with predominantly low-to-middle 2019 credit-information coverage, not economies in general.

Several explanations remain open. First, in thin formal systems, account ownership and digital-payment use may mark entry into formal finance rather than provide an incremental lender-legible signal. Second, retail lenders may lack the systems to process payment records even when such records exist. Third, realised borrowing combines borrower demand, selection and lender supply; a survey outcome cannot separate them. Fourth, coverage is an imperfect historical proxy and payment measures are qualified-comparable rather than identical. Finally, firm and retail lending technologies may use payment information in different ways.

The present evidence does not choose among the remaining explanations, but it does narrow them. A channel operating specifically through formal-lender use of payment-based credit information is difficult to reconcile with a placebo interaction of similar size and significance on a channel where no such information use is possible; that specific account is therefore not merely unconfirmed but actively disfavoured by the evidence. Account-access selection, general economic development, lender processing capacity, supply-side rationing, record usability, measurement and firm–retail lending-technology differences all remain compatible with what is observed. Direct mechanism evidence would require applications, approval/rejection, lender type, loan terms, account-opening timing, payment-record access or actual underwriting use.

The result also does not overturn the firm-level literature. The benchmark differs in unit, outcome, moderator and lending technology. The appropriate inference is narrower: a firm-level substitution pattern should not be assumed to generalise automatically to individual formal borrowing.

7 Conclusion

Digital-payment activity is positively associated with formal borrowing in the 2021 and 2024 Global Findex repeated cross-sections, and its interaction with thinner historical 2019 formal-credit-reporting coverage is negative in both waves — the opposite of what the motivating credit-information-substitution prediction implies.

The paper’s contribution is evidence against a specific mechanism rather than a confirmed boundary condition. An informal-borrowing placebo that a formal-credit-specific information-screening channel should have left near zero instead returns a positive, significant interaction of similar magnitude in both waves — evidence against that specific account, though informal borrowing is not a clean negative control, since it can still reflect social ties, reputation and selection. A parallel check allowing digital-payment activity to interact with general economic development (log GDP per capita) and the account-ownership rate erodes the formal-borrowing interaction to non-significance in both waves on the full 93-economy sample, though this is not separable from severe collinearity between coverage and development ($r = 0.74$) given only 93 economy clusters; the 2021 erosion does not survive excluding China and Saudi Arabia, where the interaction regains significance on the remaining 91 economies (§5.4), so this check carries less weight than the placebo. The reversal itself is therefore observed consistently across both waves, but its most natural specific explanation is disfavoured by the evidence and its next most natural explanation is not identifiable with this design — an empirical puzzle, not a resolved mechanism. It does not establish that weak coverage causes a negative structural effect, that payment data are complementary, or that account access, lender processing or supply constraints explain the result. Future mechanism claims would require lender- or application-level evidence.

Limitations

The evidence is observational repeated cross-sectional evidence, not an individual panel. The interaction is identified by 93 economy-level historical moderator values, not by 194,558 independent observations of institutional variation. The 2019 coverage measure is an imperfect historical breadth proxy and does not measure depth, accessibility, legal usability or lender use. The 2021–2024 payment exposure is qualified-comparable, and 2017 is contextual because its payment construct is not strictly common. The 93-economy frame is not a random or exhaustive sample of economies with available 2019 coverage data: it excludes most near-universal-coverage economies because the Findex borrowing module was not administered there (see Data), compressing the moderator’s within-sample range and narrowing the population to which the boundary-condition language applies. An inverse-probability-reweighting check (§5.4) confirms this is not merely a theoretical concern: 80 of the 132 economies with usable covariates fall outside common support

between the included and excluded groups, so the sample is classified not credibly transportable with the available covariate overlap to the excluded, mostly high-coverage population, regardless of the reweighted point estimates' own stability. The inclusion logit underlying this check still includes China and Saudi Arabia among the 93 included economies; it was not re-estimated excluding them, so the reweighting check itself has not been subjected to the same China/Saudi Arabia sensitivity analysis applied to the primary, placebo and macro-control results (§3, §5.4). The same diagnostic also shows the coverage interaction attenuates by 31–39% and loses conventional significance once digital-payment activity is additionally allowed to interact with log GDP per capita and the account-ownership rate. Coverage and log GDP per capita are themselves highly correlated across the 93 economies ($r = 0.74$), so this attenuation is consistent with either genuine development-level confounding or with collinearity-driven loss of precision from asking 93 clusters to identify two highly overlapping economy-level dimensions at once; this design cannot adjudicate between the two, so the coverage interaction's specificity to credit-information coverage, rather than economic development more broadly, is not identified here. The 2019 coverage series' Doing Business provenance also carries a disclosed, unresolved measurement-integrity question for a subset of economies, including two in this sample (see Data); excluding those two economies (China, Saudi Arabia) and re-standardizing the moderator over the remaining 91 leaves the primary interaction, the informal-borrowing placebo, and the macro-control interaction check all qualitatively unchanged (§3, §5.4), so this is a disclosed provenance concern rather than one shown to drive any reported result. A placebo check on informal borrowing (§5.4) does not pass: the coverage interaction is positive, not null, in both waves (2021 +1.95 pp, 2024 +1.75 pp, both wild-cluster $p < 0.01$), which further weakens any reading of the formal-borrowing interaction as confirming a credit-information-specific substitution effect. Account ownership may be a mediator, collider or selection variable. Realised borrowing does not distinguish demand from supply. The 93-economy, 2021–2024 sample and specification were developed during exploratory analysis of the data rather than fixed by a prospective, hash-frozen pre-registration; no such pre-registration exists for this design, and the frozen H-000501 protocol that otherwise governs this project explicitly places multi-wave/panel estimation of the outcome out of scope pending a new pre-registration process, which this analysis did not undergo. The reported estimates should therefore be read as exploratory/observational evidence rather than a confirmatory pre-registered test; they are independently reproduced at the level of arithmetic (Stage 12) but not confirmatory in the pre-registration sense. Agreement between AI implementations is computational reproducibility rather than independent human replication. These limitations are not resolved by persistence across waves or by robustness checks.

Data availability, ethics, and conflicts of interest

Data availability. The analysis uses the publicly available Global Findex Database 2021 and 2025 microdata (World Bank, 2025) and the archived World Bank Doing Business *Getting Credit* indicators (World Bank, 2019), both obtainable from the World Bank Microdata Library and Doing Business archive respectively; the raw survey microdata are not redistributed here in accordance with the World Bank Microdata Library's dataset-

use terms. All estimation and data-construction code, the aggregated (economy- and coefficient-level) results underlying every table and robustness check, and exact provenance (official catalogue links and SHA-256 hashes) needed to re-download the source microdata and rebuild the frozen analytical dataset (194,558 observations, 93 economies, SHA-256 78938AFF518F3F3BC049A18E7B8CA5C1042996392B1ACDD6EAAB56FC555240C1) from scratch are openly available at <https://github.com/Lamno1/Findex>.

Ethics. All microdata are secondary, de-identified, publicly released survey data with no individual identifiers; no new human-subjects data were collected for this study, and no separate ethics/IRB approval was required.

Conflicts of interest. The author declares no financial or non-financial conflicts of interest related to this work.

AI-use disclosure

AI systems assisted with data engineering, estimation, auditing and typesetting under author direction. Cross-agent agreement is reported as computational reproducibility, not independent human replication. The author selected the question, approved the contracts, reviewed the outputs and remains responsible for all claims and errors. No AI system is an author.

Research provenance, exploratory status, and reproducibility

The 93-economy, 2021–2024 common-frame sample and specification were developed during exploratory analysis of the underlying Global Findex data, not fixed in advance by a prospective, hash-frozen pre-registration. No pre-registration record exists for this design in the project’s hypothesis ledger, and the frozen H-000501 protocol that otherwise governs this project explicitly lists multi-wave/panel estimation of the outcome as out of scope pending a genuinely new pre-registration process, which was not carried out before this specification was chosen and estimated. This paper’s reported associations are therefore exploratory/observational evidence, not a confirmatory pre-registered test, and should be read accordingly.

What was frozen, and when, is nonetheless disclosed precisely. The analysis contract and analytical dataset were hash-recorded after the specification was chosen: the frozen analytical dataset contains 194,558 observations in 93 economies and has SHA-256 78938AFF518F3F3BC049A18E7B8CA5C1042996392B1ACDD6EAAB56FC555240C1. Stage 5 and Stage 5.1 result artifacts record the estimator, weights, clustering, bootstrap settings, specification hierarchy and result checksums, so the arithmetic reported here is fully traceable to those immutable artifacts; no new estimation was performed for this rewrite. Tables 1 and 2 are generated directly from those Stage 5/5.1 artifacts by `code/study_05_crosscountry/tables/build_stage8_tables.py` (Stage 15); no coefficient, standard error, *p*-value or sample count in either table is typed by hand. An independent forensic replication (Stage 12) rewrote the data-construction and estimation code from scratch, without reusing any of the code above, and

closely reproduced the primary 2021 and 2024 coefficients, the pooled and triple-interaction estimates, and all 186 leave-one-economy-out signs. This establishes computational reproducibility of the numbers reported; it does not establish that the sample or specification was locked before results were seen, which remains a separate, unresolved provenance question and is stated plainly above rather than obscured by the reproducibility result.
